## **Executive Summary**

Windfarm developers are obliged by law to undertake pre and post-construction surveys of the seabird population at and in the vicinity of proposed windfarm sites. The two standard tools for these surveys are aerial and ship-based surveys. Of these two, aerial surveys are the more affordable, and provide the most practical and cost effective means for gathering contemporaneous data on a large area due the limited speed of boats.

In a previous COWRIE study, HiDef Aerial Surveying Ltd. demonstrated the feasibility of applying high definition video technology to seabird surveys through trial surveys. This trial demonstrated the ability to use the HiDef surveying technique for surveying sensitive species such as common scoter in shallow waters.

In order to demonstrate the techniques capability further, to further show the feasibility of using the technique for such sensitive species in inshore areas and to provide further confidence in the technique as a practical tool for windfarm surveying, COWRIE commissioned a further trial in the Rhyl Flats area. This trial was successfully completed over two days in April 2009. The objective of this report is to record and analyse the output from this trial.

The aim of this trial was to demonstrate the ability to identify red throated divers from video data. Example images of divers are shown in section 3.3. A total of 15 divers were identified using the HiDef survey technique giving a population estimate of 75. This is in line with the population estimates described in 'Aerial Surveys of Waterbirds in Strategic Wind Farm Areas: 2004/05 Final Report (May 2006)'.

---

## **Glossary**

High Definition – an enhanced resolution video, giving a resolution of 1080x1920 pixels (approximately 2.1 mega-pixels)

## **Acronyms**

HD – High Definition

## **1. Introduction**

Windfarm developers are obliged by law to undertake pre and post-construction surveys of the seabird population at and in the vicinity of proposed windfarm sites. The two standard tools for these surveys are aerial and ship-based surveys. Of these two, aerial surveys are the more affordable, and provide the most practical and cost effective means for gathering contemporaneous data on a large area due the limited speed of boats.

In a previous COWRIE study, HiDef Aerial Surveying Ltd. demonstrated the feasibility of applying high definition video technology to seabird surveys through trial surveys. This trial demonstrated the ability to use the HiDef surveying technique for surveying sensitive species such as common scoter in shallow waters.

In order to demonstrate the techniques capability further, to further show the feasibility of using the technique for such sensitive species in inshore areas and to provide further confidence in the technique as a practical tool for windfarm surveying, COWRIE commissioned a further trial in the Rhyl Flats area. This trial was successfully completed over two days in April 2009. The objective of this report is to record and analyse the output from this trial.

### **1.1 Objective**

The purpose of this trial was to demonstrate the ability to recognise red throated divers from video data.

## **2. Video Survey Technique**

Development of HiDef's technique commenced in August 2007, with a trial flight based on a helicopter deployed gyroscopically stabilised system. Although this system had few technical features in common with the current HiDef system, the basic principles were confirmed: video was found to have sufficient detail to detect and identify even smaller birds and the survey pattern (fixed camera, parallel transects) was defined.

A second trial was undertaken in March 2008 to test developments arising from observation made during the first trial. These developments improved the image quality and streamlined the survey process. This demonstrated the deployment of a camera from a plane rather than a helicopter and the ability to survey common scoter without flushing from 2000ft. The data set showed a good agreement with past data gathered using the conventional technique.

As a result of learning from this trial, a formal methodology for video survey of waterbirds was developed by HiDef in conjunction with JNCC. This document (included as Appendix 1) sets a method and standard for gathering raw video data to the quality required for underpinning population variation analysis.

HiDef has continued to refine the survey system following the initial trials and now operates a unique purpose designed super high definition camera system which maintains the image quality achieved during the second trial, while increasing the coverage rate substantially. This camera system is integrated with an industrial data management system to provide a robust airborne camera survey system. Field trials of this system have demonstrated its ability to meet or exceed the performance requirements specified in the JNCC accepted methodology.

In comparison with the standard high definition cameras used in the trial surveys, the HiDef super high definition system has many times the megapixel resolution, and covers a far wider swathe of water, enabling us to use the same transect patterns employed by visual observers.

### **2.1 Equipment Specification**

HiDef have developed a unique, super high definition digital imaging system capable of being deployed in a range of aircraft with a suitable viewing opening. The airborne component of the system incorporates multiple digital cameras and data management equipment. The system is complimented by a ground based component that is used for data management and review of captured data.

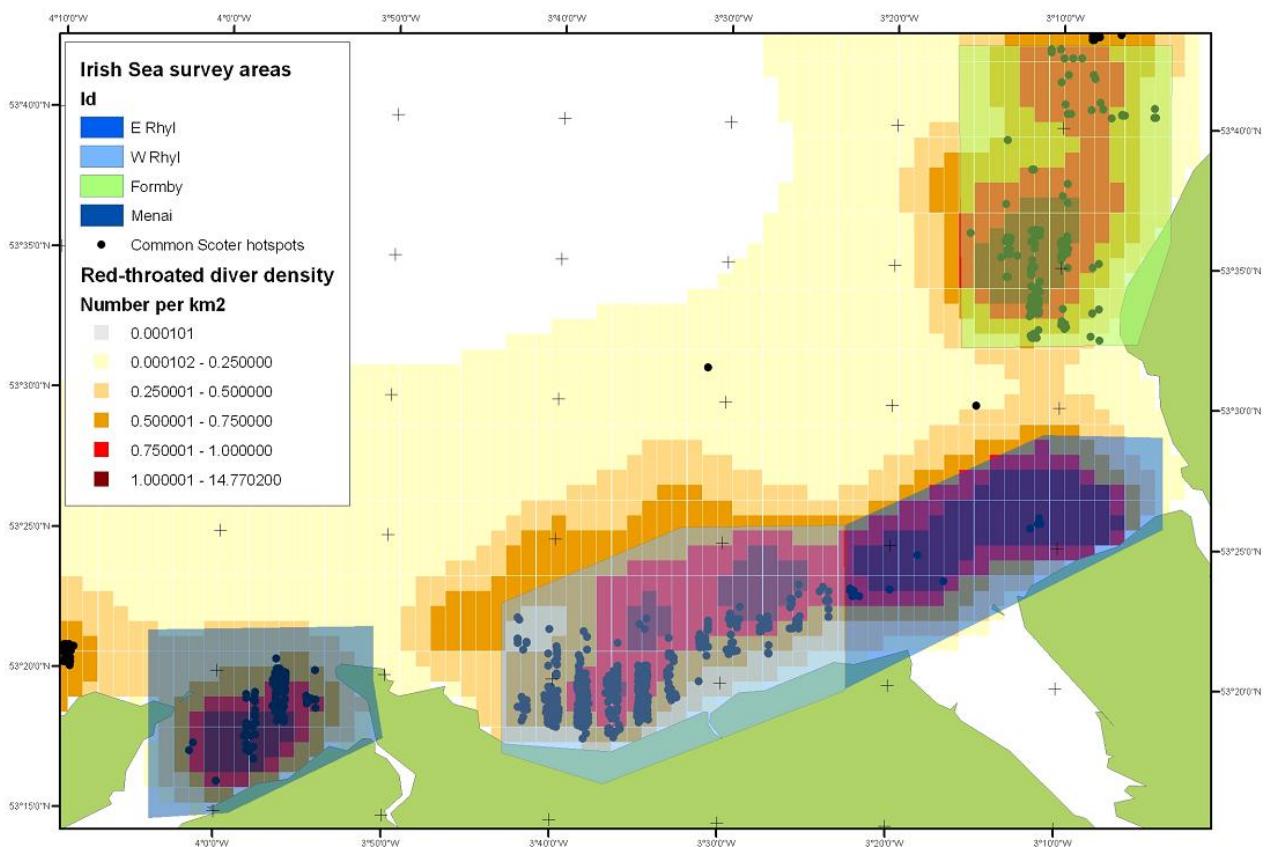

Throughout this survey, HiDef operated a bank of cameras in a fixed forward looking position directed at a steep angle. The cameras provided 2cm resolution over a 400m swathe of water on each transect flown.

The system is operated by a single technician who continuously monitors the focus and exposure. Exposure time is kept below 1/1000 seconds to eliminate motion blur and to enable high speed flying.

For more information see Appendix 1 – Aerial Survey Methodology.

## 2.2 Survey Specification

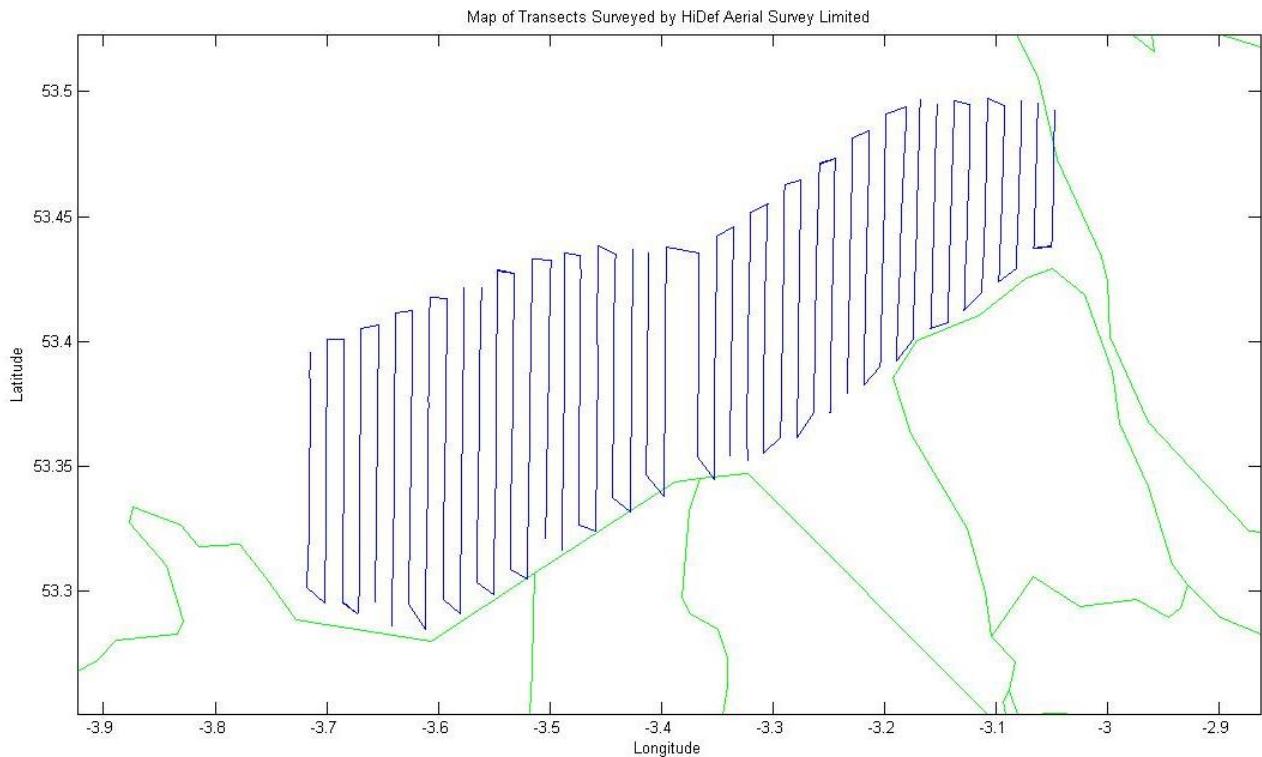

The survey described in this report was carried out in the Rhyl Flats area. Following discussions with JNCC it was decided that HiDef would cover two of the four areas on the map shown in figure 1 at 20% coverage or higher. The intention was to cover Formby and West Rhyl by preference, particularly Formby which has a relatively static population. However it was noted that, in the event that weather deteriorates while on survey, HiDef may move to one or both of the other sites to maximize the amount of good quality data that can be recorded on the day. The survey was flown at a nominal altitude of 2000ft at speeds up to 280kph.

**Figure 1** – Map of Rhyl Flats area showing possible survey locations

---

The following figure shows the transects flown in the survey:

**Figure 2** – Transects flown in the survey of the Rhyl Flats area.

### 3. Survey Implementation

The survey detailed in this report was carried out over two days on the 5<sup>th</sup> and 8<sup>th</sup> of April. The survey transects were flown North to South throughout the two days. On the whole the weather conditions were good; however, it was noted that when the plane was flying south, there was sometimes a large amount of reflection of the water surface causing the data to be more difficult to review.

#### 3.1 GPS Track

The surveys were carried out in line with the original specification with both West Rhyl and Formby being surveyed. The surveys achieved 20% coverage of the area.

#### 3.2 Data Quality

As noted above, the survey transects were flown on a North South axis. The south flying transects were flown into the sun and, as such, there was found to be significant reflections off the water which caused difficulties in review of the data. This principally caused the initial review of the data to be elongated; however, it was noted that in some cases it would be unlikely to have been able to successfully identify some of the smaller birds. The data which was generated on the North flying transects was generally of good quality.

Audits are carried out on all the data which HiDef reviews. This involves 20% of the raw data over the complete range of the data being reviewed for a second time by a competent reviewer. The output of the two reviews are then compared and any discrepancies are noted. If there are any significant differences between the reviews, further training is given to the affected reviewers and the data previously reviewed by those reviewers is re-reviewed by a competent reviewer.

---

During the review of this data, we found that there was one reviewer from whom there were significant discrepancies. As a result of this, the reviewer was given further training and the data they had previously reviewed was re-reviewed.

### **3.3 Example Images**

Example images of the main species of interest within the survey area are shown below. It should be noted that each image represents a very small portion of the frame from which it was extracted.

Picture 1 – A Red Throated Diver

---

## **5. Discussion**

The aim of this trial was to demonstrate the ability to identify red throated divers from video data. Example images of divers are shown in section 3.3. A total of 15 divers were identified using the HiDef survey technique giving a population estimate of 75. This is in line with the population estimates described in 'Aerial Surveys of Waterbirds in Strategic Wind Farm Areas: 2004/05 Final Report (May 2006)'.

The majority of the birds identified in the Rhyl flats area were scoter. There were also a large number of gulls and a not insignificant number of auks. As shown in the previous section the majority of bird species were spread relatively evenly across the area with the exception of the common scoter which were grouped in quite a close area near to the shore.

## **6. Data Tables**

The following table shows the main output form the high resolution survey of Rhyl Flats.

Location	Survey Date	Camera	Time	Reel Ref	Frame Ref	Category	Confidence	Number	Behaviour	Latitude	Longitude
Rhyl	05/04/2009	1	10:01:00.000	14.44.09.312	2783	Fulmar	Moderate	1		53.3207175	-3.7007639

# **Appendix 1: Aerial Survey Methodology**

## **A Methodology for Surveying Waterbirds Using Video**

### **Introduction**

Aerial surveys have proved an invaluable tool for quantifying and monitoring waterbird populations at offshore wind farm sites. Existing techniques, utilising expert visual observers, have the advantage of being able to cover large areas economically. However, due to the relatively low altitude typically employed in these surveys (80m), it is not yet possible to survey the footprint of built wind farms using this technique in the UK. Furthermore, the technique is known to disturb several species, and this disturbance can complicate the analysis of the data, causing wide confidence intervals in population estimates, and hence low probability of detecting a change in the local population.

Video based surveying techniques have been developed in order to avoid these two key problems caused by low survey altitude. By replacing the visual observer with camera and telephoto lens, the surveys can be conducted from altitudes in excess of 3000ft. It has been found that more sensitive species such as Common Scoter are not disturbed by a light aircraft flying at 2000ft, so video methods are able to make non-invasive observations of waterbirds. The resulting raw data sets, comprising a series of digital video frames, each stamped with time and GPS coordinate, provide a permanent record of the survey area at a particular point in time and can be reviewed and audited offline at leisure. This eliminates the need for estimation of bird numbers and other sources of subjectivity that can increase confidence intervals.

### **Limitations of current aerial survey techniques**

Dean *et al.* (2003) reviewed current aerial survey techniques, later described by Camphuysen *et al.* (2005), and identified a number of limitations with techniques used at the time:

1. Due to the low survey height, aerial survey coverage cannot be extended right up to the shoreline in many areas, especially in populated areas, or areas where the coastline consists of tall cliffs. Many areas close inshore are particularly important for grebes, greater scaup, common goldeneye and red-breasted merganser – significant numbers of these are likely to be missed if the aircraft is required to turn at, or before the shore is reached.
2. due to airspace restrictions, aircraft cannot enter some areas at some times, making it difficult to cover some areas in their entirety – significant numbers of birds may regularly aggregate in restricted areas;
3. the minimum cruising speed of 100 knots, combined with the low survey height, mean that observers have minimal time to scan a passing area of water (far less than in ship-based surveys) and that the bird encounter rate is much higher. This is likely to result in birds being missed, particularly inconspicuous, rare, or scarce species;
4. similarly, there is often insufficient time for observers to accurately identify species, resulting in significant numbers of sightings recorded at less specific taxonomic levels and possibly a degree of miss-identification, particularly for divers, grebes and scoter, and especially where mixed species flocks are encountered;
5. there is often insufficient time for observers to accurately record numbers, or to consistently record the age, sex, or behaviour of birds;

- 
- 6. it is difficult to collect additional data on the biological or hydrographic factors that may influence waterbird distributions.
  - 7. the short time available to observers reduces the precision of distance estimation (can't use as many distance bands as boat-based surveys) and is also likely to reduce the accuracy of distance estimation (more birds incorrectly assigned to distance bands);
  - 8. precision of locations assigned to observations for aerial surveys is less than for boat-based surveys due to greater speed and time recording errors;

Some of these could be addressed by improvements to the visual detection methods. However, many cannot be addressed, and it is with these shortcomings in mind that the video survey methods are described here.

## **Survey Specification**

Although similar in intent, due to the limited field of view of a video camera, the video survey methodology differs somewhat from that of the visual method. Unlike visual observers, video systems vary significantly in their capabilities, and the survey specification must be adapted to the performance of the cameras that are being employed.

Digital video cameras are developing very rapidly at the time of writing, with significant increases in image resolution and quality likely in the next few months. For this reason, the survey specification set out here does not call for any particular camera or family of cameras. Rather, the survey parameters are expressed relative to camera properties, with minima and maxima imposed on some parameters for statistical reasons.

### *Transect pattern:*

As with visual surveys, a series of line transects are employed. Unlike visual surveying, there is no need to use a detection function to estimate the numbers of seabirds missed at different distances from the line; each transect captures a strip of sea, in which all birds have an equal probability of detection. Sufficient video quality to ensure that birds are not missed is readily achieved, and the probability of detection within this strip is therefore assumed to be equal to one, the risk of this assumption being violated is thought to be minimal (A. Webb pers. comm.). Even very high resolution cameras result in narrower transects than can be achieved by visual observers.

As with any transect sampling approach, some care must be taken to ensure that the survey is representative of the whole population. These considerations are identical with conventional surveys, and include random location of the transects, i.e. not defining the transects with respect to features that could potentially correlate with bird location (including wind farms), and surveying perpendicular to depth contours where possible.

Often it is necessary to curtail transects within a particular distance of the coast because of low-flying height restrictions or because of sea cliffs. In the absence of such restrictions, any transects that meet land video survey should continue fully onto the land to ensure that the sample includes the surf zone.

### *Coverage:*

Coverage is the term used to describe the proportion of the survey area that is actually sampled. In the case of video surveys, this can readily be understood as the proportion of the survey area that falls within the field of view of the camera at some point during the survey.

---

In the case of conventional surveys, coverage does not have a simple definition. For 2km transect separation, every part of the survey area is nominally visible. However it is certainly not the case that every bird is detected; in practice, the vast majority of observed birds are seen within the first 200m of either side of the aircraft, and the number of birds observed per unit area drops rapidly as a function of distance from the aircraft. An approximate coverage can be calculated on a per species per survey basis by dividing the number of observed birds by the population estimated using distance sampling, which typically yields figures in the 15-30% range. However, even these figures do not provide a fair comparison with coverage as defined for video methods, because significant statistical manipulation is required to account for uncertainties introduced by estimation of flock size and model fitting.

The absolute lower bound on the coverage of a video survey should be 10%; this is effectively equivalent to conducting a conventional survey in which only the observation band closest to either side of the aircraft (100m) is recorded. This implies that for a given image width  $W$ , the transect separation should be a maximum of  $10*W$ , as shown in Figure 1. As an example, the 40m image width achievable with a high definition video camera results in a maximum transect separation of 400m.

Because birds are not displaced by the survey aircraft, video surveys can utilise narrow transect separations that are not available with visual surveys. This enables coverage to be increased up to 100% if required for very high accuracy surveys, and even allows multiple pass surveys. Ultimately, the objective of a survey is to estimate the population of given species at a given time and location with sufficient confidence that a significant change in population can be detected. The confidence intervals associated with any population estimates are driven not only by the survey parameters, but also by the distribution of birds themselves; surveys for less numerous species will tend to yield population estimates with larger confidence intervals than surveys for more numerous species. The coverage rate should be adapted so that the population estimates for all species of interest have sufficiently narrow confidence intervals to provide a high certainty of detecting any change over time. The target coefficient of variance for a population estimate should be 0.3 or better.

Note that for video surveys it is not just the aircraft but also the camera that determines the transect. By changing the orientation of the camera it is possible to change the transect that is being sampled. Similarly, multiple fixed cameras with different orientations can sample different transects simultaneously from the same aircraft.

*Altitude:*

Survey altitude is a trade-off between image quality and the need to avoid disturbing birds or having to break off a transect early to avoid a collision hazard. Lower altitude results in better image quality due to reduced haze and increased available light, which in turn gives lower noise and/or better depth of field.

It has been found empirically that when flying at 2000ft, even the more sensitive species, such as Common Scoter, do not visibly react to the aircraft. At lower altitudes some birds begin to alter behaviour, with flushing occurring at around 700ft. In order to provide a comfortable margin of safety, an absolute lower limit of 900ft is placed on survey altitude.

*Speed:*

---

An important feature of video data, as opposed to still images, is that multiple observations of each bird are made over a short time window. These multiple observations provide insight into bird behaviour, and enable real birds to be distinguished from short lived patterns in the water which momentarily appear similar to birds. In particular, multiple observations enable estimation of the direction and height of flying birds.

Around half a second of video is sufficient to estimate these basic features. The duration that each bird spends within frame is determined by the velocity of the aircraft and the depth of the video image. To ensure a sufficient number of independent frames are captured, each bird should appear in a minimum of ten frames, over a time period of no less than 0.4 seconds. This is equivalent to flying at a velocity of 180 kph, with a 20m deep image (1000 pixels at 20mm per pixel) and a frame rate of 24 frames per second. Increasing the frame rate above 24 fps provides only a minor increase in information as it does not extend the period each bird is in frame for.

*Weather:*

As with conventional surveys, video surveys are dependent to an extent on suitable weather conditions. The greatest single factor affecting the video methodology is cloud-base; in order to meet the 900ft minimum altitude criterion, the cloud base needs to be at 1000ft or more.

Visibility requirements are typically comparable to those of a conventional survey; although the cameras sometimes look through a greater thickness of air than visual observers, vertical visibility is often better than horizontal visibility on the same day, and the ability to slow down video and adjust contrast mitigates the reduced clarity of the image.

The video technique is relatively robust to sea state and wind speed. The greater altitude during video surveys results in much steeper observation angles, which in turn mean that even in high seas, birds (or mammals) are unlikely to be hidden in the troughs of waves. In visual surveys, where peripheral vision is required to pick up on birds in the first instance, white caps and spume can cause serious visual distractions resulting in missed birds. In the case of video, however, the ability to slow down and replay the video means that while such features increase the data processing effort, they do not necessarily affect the quality of the output. Maximum sea states and wind speeds for the technique are not known; however, there is a need to keep these parameters close to those experienced during visual surveys so that the two data sets remain as compatible as possible. For this reason, the maximum recommended wind speed is 30km/h.

## **Video Specification**

The video effectively takes the place of a human observer as the sampling tool. The basic requirements of the video system are that the individual images are of sufficient resolution and quality to enable detection and identification of birds, and that each frame should be associated with a location. Video technology is developing rapidly with promising new systems for aerial surveying likely to come onto the market over the next eighteen months. This specification does not therefore demand a particular video system. However, it should be noted that systems with lower resolution than the 1920 by 1080 pixels of current high definition video systems are unlikely to prove economic, and generally speaking, the higher the resolution the more economic the surveys become.

*Image size:*

---

The fundamental property of the system that determines the quality of the data is the size on the ground of an individual pixel. It has been found that a pixel size of 20mm (i.e. each side of a square pixel corresponds to a 20mm distance in the imaged scene) gives sufficient detail to identify birds to the required level of accuracy. It is possible that a decrease in size to, say, 10mm or less may provide sufficient detail to distinguish Guillemots and Razorbills, for example, but the benefits are considered to be outweighed by the significantly increased cost with current technology. Ultimately, the pixel distance used should meet the requirements of the survey.

The pixel size combined with the camera resolution generate an image width, i.e. an image 2000 pixels wide, with each pixel 20mm across, will generate an image 40m wide. The width and height of the image are fundamental parameters of the technique as they determine the maximum airspeed and transect separation, which determine the time that the plane must fly for and therefore cost of the survey.

Image size itself is determined by two further properties of the system, the focal length of the camera lens and the altitude of the aircraft. By varying these two together, it is possible to maintain a fixed image width while varying altitude, e.g. to avoid low cloud. This can be controlled in two ways. First, the zoom can be manually adjusted to keep the apparent speed of the image constant (i.e. the time it takes an object to cross from the top to the bottom of the image is held constant). This method enables complete freedom of altitude, but can result in some inaccuracies, either reducing efficiency or quality. The second approach is to have two or more fixed lenses, one for each of a set of pre-determined altitudes. The appropriate lens is installed for the chosen altitude and lenses are swapped when the altitude is changed. This results in more precise image scaling, but a significantly less flexible system. A happy medium can be obtained if a zoom lens can be identified that has useful lengths at both extremes of its range; this gives two fixed lengths which can be switched without swapping lenses and also provides the opportunity to be more flexible if required. Unfortunately lenses with an appropriate range of focal lengths are rarely available for suitable cameras, and some modification is typically required to build a working system.

Note that the exact focal length of lens required is a function of the actual physical dimension of the sensor array. As this varies from camera to camera, even for those with the same resolution, a specific focal length cannot be made part of this specification. However, an example is provided below for a particular camera system that has been shown to work well for survey applications.

#### *Image quality:*

It has been found empirically that the errors that are most damaging in terms of the ability to recognise birds are poor focus and overexposure.

Focus should typically be constant as long as altitude is held constant, and it is therefore beneficial to modify a system so that focus can be mechanically locked once the correct position is found. If this is not possible, the best approach is to reset the focus during the run-up to the beginning of each transect. This is particularly difficult when the sea is calm and may necessitate adding a period of 'dead time' to the beginning of each transect, with an associated loss of efficiency.

Exposure typically occurs when exposure is set for the sea rather than for birds. Many species of birds will appear significantly brighter than any features on the water, particularly on a clear

---

day. Setting exposure becomes easier with experience, but as a general guide it should be set as dark as possible to while still being able to resolve features of the sea.

A waveform monitor is a useful tool for ensuring that birds are not overexposed. This plots each line of the image as a line on a graph, so that small bright objects appear as sharp peaks; as long as these peaks are less than the maximum value that the camera can provide, the image will not be overexposed.

Exposure is controlled through a combination of iris and shutter speed. Fast shutter speeds are generally necessary to stop the rapid motion of the image through the frame.  $1/500^{\text{th}}$  of a second should be regarded as a minimum when flying at 185 km/hr, with  $1/1000^{\text{th}}$  of a second preferable. If airspeed is increased significantly, then  $1/1000^{\text{th}}$  should be regarded as the minimum. Iris determines focal depth and therefore the altitude at which birds lose focus. Preferably, the iris should be as small as possible to maximise focal depth, i.e. the image should again be set as dark as allowable. However, loss of focus with altitude has not been found to be a significant problem to date, even when using a relatively wide iris.

Finally, electronic gain can be used to boost the contrast of an underexposed image; this introduces noise, however survey video is typically more tolerant of noise than, say, a television production would be. The level of noise relative to electronic gain will inevitably vary from camera to camera and from day to day, however, 3dB of gain typically appears to be acceptable.

The best approach to exposure on a low light day is therefore as follows: set shutter speed to  $1/1000^{\text{th}}$  of a second and gain to 0 dB initially, and widen iris until a dark, but acceptable image is obtained. If the image remains too dark at full iris, reduce shutter speed to  $1/500^{\text{th}}$  of a second if airspeed allows, and add 3dB of gain if further brightening is required. If this image is still too dark after these steps have been followed, the survey should be terminated.

On a bright day, gain should be set to 0 dB, shutter speed to  $1/1000^{\text{th}}$  of a second and then the iris reduced until the image is suitably dark. If the image remains too bright at full iris, shutter speed should be increased, if the camera is capable. In the unlikely event that the image is still too bright, neutral density filters should be installed on the lens.

Due to the relatively long focal length lenses required to get the necessary detail and the need to fix the camera to the airframe, camera vibration can cause a significant deterioration in image quality. In all cases, some kind of stabilising mount will be required, with active gyroscopically stabilised mounts preferred for higher altitudes. Ultimately, the requirement for the mount will be determined by the aircraft and altitude; the mount should eliminate detectable vibration induced blur in the still frames.

#### *Camera orientation:*

Recognition is facilitated if the camera does not look directly downward, so that the profile of the bird can be discerned. However, relatively steep angles have the advantages of minimising distance between the camera and the target (improving image quality), of ensuring that the birds are not obscured in wave troughs, of minimising glare, and of enabling the camera to see submerged details.

---

The direction that a camera points is relatively unimportant, provided that the direction is known, so that the position of each image can be calculated with sufficient accuracy. Camera orientation should therefore be recorded to at least +/- 0.5 degree accuracy.

If multiple cameras are used in a single aircraft, orientations should be selected so that each camera is separated from the others by a sufficient distance to prevent birds observed by one camera entering into the field of view of another. 100m centre-to-centre separation is sufficient. This arrangement results in a data set that is simpler to work with and provides a more even coverage of the survey area.

The final requirement is to select an appropriate roll for each camera. Roll should be chosen so that the image appears to travel directly from the top to the bottom of the screen, without any diagonal element. Forward pointing cameras should have no roll, so that the horizon is parallel with the top of the frame, while sideways pointing cameras should be positioned so that the horizon is parallel with the side of the frame. Intermediate positions will require an intermediate roll.

*Sampling:*

In order for the data to be statistically tractable, the centre line of the video is treated as the sampling point. The timecode and GPS location associated with each bird should be those of the frame in which it is closest to the midline. Maximising the useful data according to this criterion is the reason for adjusting the role of each camera, as described in the previous section.

*Data recording:*

The data recorder should be capable of recording a full days surveying without the need to break off the survey. The two viable options at this point in time are digital tape systems, and multiple hard drive server systems. Both have pros and cons; tape recorders are expensive, cause some deterioration of the data and the tapes must be manually changed four or more times per survey, however they minimise handling of the data as the survey tapes themselves can be readily used for review and archive. Hard drive systems are bulky and usually require data to be converted into a secondary format for transport and archival, but can record uncompressed and do not necessarily require any manual intervention during the survey.

**Example system**

*Hardware:*

Camera: Sony F950 mounted in a Cineflex gyroscopically stabilised mount.

Aircraft: Diamond DA42 MPP twin engine plane with nose pod to carry camera.

Data recording: Sony S280 HDCAM format tape recorder.

*Camera set up:*

---

Lens: focal length set to 150mm, to provide an approximately 40m image when flying at 2000ft. Preferably locked.

Orientation: pointing straight forwards and down at an angle of 35 degrees from vertical. Preferably locked.

Exposure: shutter speed set to 1/1000<sup>th</sup> of a second, and iris adjusted to give darkest acceptable image. Waveform monitor used to inspect exposure during survey.

*Survey Specification:*

Transects: straight and parallel, separated by a centre to centre distance of 400m to give 10% coverage. Transects staggered by 300m, depending on direction of flight, to account for the fact that the camera looks at an area 300m ahead of the plane. Each transect to have a further 500m 'dead space' at the beginning to provide approximately 10 seconds focus adjustment time (unless that transect begins on land). Other than altitude and separation, survey design should follow the general guidance provided by Camphuysen *et al.* (2005).

Airspeed and altitude: 185 kph at 2000ft.

## **Data Review**

The video data is reviewed off-line at any time after the survey. The video is played back at a speed that will allow the observer to comfortably detect every bird. Preferably, the playback system should provide the user with a reasonable degree of control over playback speed. Under calm flat conditions with favourable light, it is often possible to detect birds as the video is played back in real time.

It is not necessary to be able to identify birds to species level at the playback speed, provided that forward and reverse slow motion and pause functions are available on the player. These enable the observer to carefully assess each bird.

The simplest way to record the data is to list each observation in a spreadsheet, with date and timecode at which the bird crosses the midline of the image, species, any notes on behaviour, camera (if using a multi-camera system) observer identity and review date. Timecodes and camera identities can then be converted into coordinates using the plane GPS location and known camera geometry. Slightly greater accuracy of location can be achieved if the precise location of the bird in the frame is recorded, but the improvement is typically only of the order of a few metres, and is unlikely to repay the effort in most applications.

Data review can be a physically and mentally demanding task. Unlike visual surveys, the observers eyes are held at short focus and are relatively stationary while reviewing the data. Reviewing sessions should therefore be broken into short chunks that are not sufficiently long to induce discomfort, and these should be separated by breaks of a sufficiently long period to rest the eyes. Suitable stints and breaks are likely to vary with individuals and data, however 30 minute stints with 5 minute breaks may prove suitable as a target. During breaks, the observer should preferably focus on objects at some distance to reduce stress, particularly on the eyes.

---

To ensure quality, a proportion of the data should be reviewed by two independent observers that are highly experienced in detection and identification of seabirds from the air. Neither observer should be aware of the other's findings, nor the sample to be checked should consist of randomly selected transects.
